Abstract—The agglomeration of particles is a process that modifies the physical properties of a product originally manufactured as a powder. During milk powder agglomeration of fluidized bed, resulting agglomerates are sufficiently porous to improve the solubility of the final product but, at the same time, their rigidity decreases and agglomerates can be destroyed during packing. The porosity and rigidity properties depend on both the volume and shape characteristics of the agglomerates. This paper presents a three-dimensional reconstruction technique based on a laser displacement sensor (LDS) applied to characterize milk agglomerates. This technique allows three-dimensional scanning to estimate particle volume and extract shape parameters such as: sphericity, elongation and flatness ratio, shape factor and aspect ratio. This technique was implemented using a mechatronic device with two degrees of freedom. The device is composed of an angular positioning system to rotate the agglomerate and a linear positioning system to displace the LDS. Experimental result allows agglomerates classification according to shape parameters.

Keywords—agglomerated particles; laser displacement sensor; shape parameters; three-dimensional reconstruction

I. INTRODUCTION

In the food industry the agglomeration process of powders increases the particle size as well as its porosity and then modifies end-user properties such as wettability, sinkability, dispersibility and solubility. The main application of agglomeration is to produce instant products (e.g. instant coffee, milk powder, cocoa beverages, etc.) that acquire the ability for dispersing or rapidly dissolving in liquids (water, milk, etc.)\textsuperscript{1}.

Furthermore, many of the physical and structural properties of agglomerates such as density, surface properties, size and shape, influence the particles rigidity and then modify their behavior during handling [2,3]. The measurement of these physical properties is important since they affect the behavior of powder particles during storage, packing and processing.

The size parameter (usually associated to diameter, surface area or volume) describes the geometry of the object regardless of its form \cite{4}. The shape parameter characterizes the object regardless of the size. Currently, the measurement of the shape parameters of agglomerates is performed from 2D data, usually from microscope images. One of the shape parameters frequently used in the characterization of objects is the sphericity. However, there are no works to report measurements of sphericity in the characterization of agglomerates of milk powder from 3D data.

There are different methods for characterization of agglomerated particles. In \cite{5} the shape of agglomerates is computed from 2D microscope images by finding the circle that best fits the estimated area on each image, assuming that particles have a circular shape. A highly accurate technique is the use of confocal microscopy \cite{6} that creates sharp images of a specimen, normally blurred with conventional microscopes; however, stimulating fluorescence from dyes that should be applied to the specimen, can modifies the agglomerates properties. Another method to characterize agglomerate is the use of mercury porosimetry applying various pressure levels to the sample. This technique is not suitable to characterize agglomerates, normally fragile, that are broken during the measurement \cite{7}.

The work presented in \cite{8} computes the porosity of fragile agglomerates from only three images acquired with a CCD camera. The work described in \cite{9,10} present a method based on silhouettes extraction of multiple views to estimate the volume of the envelope of milk powder agglomerates; agglomerates concavities are not considered. The works in \cite{11-13} developed methods to estimate the shape of particles using 2D shape parameters from image analysis techniques.

The aim of this paper is to propose a methodology to characterize the shape of agglomerated particles of milk powder using 3D parameters. This methodology is based on a laser displacement sensor that allows a three-dimensional reconstruction of the agglomerated particles. This approach can be extended to measure other particle systems. The shape of the agglomerates was analyzed using the following form factors: elongation, flatness, aspect ratio and sphericity. Also, the particle volume is determined since it is used as a basic parameter to determine the particle sphericity.
II. 3D RECONSTRUCTION SYSTEM

A. Positioning System

The positioning system is shown in Fig. 1. The agglomerate is placed on the object holder that rotates, driven by a stepper motor, at $\Delta \theta$ degrees increments controlled by a PIC-STEP control board. The laser displacement sensor (LDS) is rigidly mounted on a linear positioning system that moves along $z$-axis at $\Delta z$ increments ($\Delta z = 30 \mu m$).

B. LDS Description

The LDS used works on optical triangulation principle. A laser diode (wavelength 650 nm) is the light source, projecting a spot onto the surface to be measured. The LDS is mounted on the linear positioning system. The LDS controller estimates the distance between its emitter and the target (agglomerate surface). Fig. 2 shows the laser triangulation principle.

C. Principle of Distance Estimation

Fig. 3 illustrates the sensor principle to estimate the distance to target where:

\[
d_L: \text{Distance to laser},
\]

\[
d_D: \text{Distance to detector},
\]

\[
\beta: \text{Angle of incidence},
\]

\[
d_E: \text{Speculate distance},
\]

\[
I_D: \text{Intensity on detector},
\]

\[
x_L: \text{x-axis component of incident laser beam},
\]

\[
y_L: \text{y-axis component of incident laser beam},
\]

\[
x_D: \text{x-axis component of reflected laser beam},
\]

\[
y_D: \text{y-axis component of reflected laser beam},
\]

By geometry, we obtain the following equations for the distance to the laser and the angle of incidence:

\[
d_L = \sqrt{x_L^2 + y_L^2}
\]

(1)

\[
\beta = \arctan\left(\frac{x_L}{y_L}\right)
\]

(2)

and the distance to the CCD:

\[
d_D = \sqrt{x_D^2 + y_D^2}
\]

</tr>
</tbody>
</table>

The measurement technique is based on the LDS model LK-G10 from KEYENCE. TABLE 1 shows the technical specifications of the sensor.
According to the law of reflection, the reflected beam has the same angle that the incident, so we have:

\[
x_L = \frac{x_D}{y_L} = \frac{y_D}{y_L}.
\]  

(5)

The normal density function (Gaussian curve), in Fig. 3, represents the laser beam intensity detected by the CCD and corresponds to the distance to the specular (d_E) from the laser to the object surface. This distance is defined by:

\[
f(x - \mu) = \frac{1}{\sigma \sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}},
\]  

(6)

where \( \sigma \) is the standard deviation and \( \mu \) is the average intensity obtained by the CCD detector.

Fig. 4 shows how a variation (\( \Delta y \)) in the distance to the object’s surface (displacement) produces a change in the mean of the Gaussian curve.

Fig. 4. Measuring displacement of object’s surface.

Fig. 5 shows the relationship between the displacement of the Gaussian curve \( d'_{E} \) and the displacement \( \Delta y \) is given by:

\[
\Delta y = -d'_{E} \cos(\beta)
\]  

(7)

Since the measuring range of CCD is limited, the maximal variation \( \Delta y \) is given by:

\[
\Delta y_{Max} = \frac{I_{D}}{2} \cos(\beta).
\]  

(8)

**D. Estimation of 3D Coordinates**

The purpose of distance measurement by laser triangulation is to calculate the radius (\( r \)), which is the distance from the center of the object holder to the point where the laser beam strikes the object, see Fig. 6.

Fig. 6. Laser triangulation measurement.

The object is mounted on the object holder. Fig. 6 shows a circle shaped object, the laser beam is projected onto the object surface and reflected towards the CCD. The angular positioning system rotates using a constant increment (\( \Delta \alpha = 0.9^\circ \)) which is calculated by dividing 360° by the number N of steps of the motor (N=400). The 3D coordinates of each point of the object surface, \( D_i=(x_d, y_d, z_d) \), are obtained from \( r_i \), \( i=1,2,3,...N \) and \( \beta_i \) as follows:

\[
\begin{bmatrix}
x_{d_i}
y_{d_i}
z_{d_i}
\end{bmatrix} =
\begin{bmatrix}
\cos \beta_i & 0 & 0 \\
0 & \sin \beta_i & 0 \\
0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
r_i \\
r_i \\
z_i
\end{bmatrix}
\]  

(9)

Where \( \beta_i = \beta_{i-1} + \Delta \alpha \). The value of \( z_i \) is also a constant defined by the increments of the micrometer.

**E. Shape Parameters**

The spheres and cubes are the only objects whose size can be given for only a number (diameter or length). Food powder
particles are irregularly shaped particles and their characterization requires several parameters of size and shape [11]. The shape parameters used in this work are based on the three representative lengths: $L$ (longest dimension), $W$ (intermediate dimension) and $T$ (shortest dimension) [14], see Fig. 7. These lengths are equivalent to the lengths of the sides of a solid rectangle of a particle boundary, as shown in Fig. 7.

Fig. 7. Main dimensions or an irregular particle.

The elongation ratio ($ER$) is defined in as:

$$ER = \frac{W}{L}. \quad (10)$$

For circular objects $ER$ is equal to 1. The more elongated shape, the greater is its elongation factor [11].

The flatness ratio ($FR$) and the aspect ratio ($AR$) are as:

$$FR = \frac{T}{W}, \quad (11)$$

$$AR = \frac{L}{W}, \quad (12)$$

respectively.

The shape factor ($SF$) has been used to describe the irregularity of the surface and is defined as:

$$SF = \frac{T}{\sqrt{WL}}. \quad (13)$$

From 3D coordinates of the object surface, obtained from the LDS, one can estimate the particle sphericity ($Sp$). The sphericity value varies from 0 to 1, where a value of 1 indicates a perfect sphere [14]. The sphericity is defined by:

$$Sp = \frac{d_n}{L}. \quad (14)$$

Nominal diameter $d_n$ and nominal surface $s_n$ are computed as:

$$d_n = \left(\frac{6V}{\pi}\right)^{\frac{1}{3}}, \quad (15)$$

$$s_n = \left(36\pi V^2 \right)^{\frac{1}{3}}, \quad (16)$$

respectively.

The volume $V$ and lengths $L$, $W$ and $T$ of the agglomerated particles may be obtained from the 3D coordinates estimated by the LDS.

III. PARAMETER EXTRACTION FROM AGGLOMERATES

A. Test Agglomerates

To carry out the experimental part of this work, 10 samples of milk powder agglomerates were obtained using the fluidized bed technique, see Fig. 8. The particles were divided into three size fractions by sieving: up to 630 µm for size A, up to 1250 µm for size B and from 630 to 1250 µm for size C. Prior to analysis, the agglomerates were stored for one week in a desiccator with silica gel for drying.

For weighing of the individual agglomerates, a laboratory precision balance (AX205 Delta Range, Mettler Toledo, France) was used. This balance has a precision of 0.01 mg with a weighing error that might be up to 0.005 mg. It was therefore not sufficient for individual agglomerates in the small size fraction (inferior to 630 µm). For this reason, only agglomerates larger than 630 µm were considered for the measurement of shape using 3D reconstruction method.

Fig. 8. a) Agglomerates samples, b) Zoomed view of one agglomerate.

B. Shape Parameters Estimation

The experiment was conducted at an ambient temperature of 24°C. The agglomerate was mounted on object holder, as shown in Fig. 9. Ten repeated measurements were performed. The LDS was placed at a distance of 10 mm to the center of the object holder.
Agglomerated particles were scanned using the three dimensional reconstruction technique based on LDS as shown in Fig. 9. Based on the representative three lengths: $L$, $W$ and $T$, were determined to describe the shape parameters presented in TABLE 2. It is evident that the agglomerates are near to spherical. The agglomerates are the extreme case, in which variations of volume, surface area, $ER$, $FR$, $AR$, $SF$, and $Sp$ depend on the form of agglomerates due to irregular shape.

IV. CONCLUSIONS

This paper presents an experimental validation of a 3D reconstruction technique of milk powder agglomerates based on a laser displacement sensor. This technique allows the estimation of the particles volume ($V$) and surface ($s_n$) as well as some size lengths ($L$, $W$, $T$) to determine some shape parameters ($ER$, $FR$, $AR$, $SF$, $Sp$). Since we have a 3D cloud of points, a textured representation of the agglomerate is also available.

As expected, the reconstructed object has errors associated with the discretization of the data. Those errors are less than 1% considering only scanning along z-axis. The experimental results demonstrate the feasibility of this technique to estimate the shape parameters of agglomerate small particles that can be generalized for other kind of objects. A better accuracy is possible simply by increasing the number of points per turn (on the angular positioning system), for example by using a DC servomotor instead of a step motor. In the same way, accuracy can be improved by reducing the increments in the z-axis using a DC servomotor to move the LSD. Perspectives for our work mainly are that the method presented could be used in combination with more complex morphological analyses [15] to validate other optical particle characterization methods [16].
